ABSTRACT: We present, for the first time, scalable polarizable molecular dynamics (MD) simulations within a polarizable continuum solvent with molecular shape cavities and exact solution of the mutual polarization. The key ingredients are a very efficient algorithm for solving the equations associated with the polarizable continuum, in particular, the domain decomposition Conductor-like Screening Model (ddCOSMO), which involves a rigorous coupling of the continuum with the polarizable force field achieved through a robust variational formulation and an effective strategy to solve the coupled equations. The coupling of ddCOSMO with nonvariational force fields, including AMOEBA, is also addressed. The MD simulations are feasible, for real-life systems, on standard cluster nodes; a scalable parallel implementation allows for further acceleration in the context of a newly developed module in Tinker, named Tinker-HP. NVE simulations are stable, and long-term energy conservation can be achieved.

This paper is focused on the methodological developments, the analysis of the algorithm, and the stability of the simulations; a proof-of-concept application is also presented to attest to the possibilities of this newly developed technique.

1. INTRODUCTION

In the past few years, polarizable molecular mechanics (MM) has been an intense field of development.^{1–8} In particular, polarizable molecular dynamics (MD) simulations open new routes to study difficult systems, ranging from metalloproteins and heavy-metal complexes to polar and ionic liquids that require more-sophisticated potentials. Moreover, an increasing number of studies show that the lack of polarization can be a serious limitation for ionic systems but also for a correct estimation of weak interactions, with direct implications in protein folding and protein–ligand binding.^{8–12}

However, the potential increase of accuracy that can be reached by introducing a polarizable force field (PFF) faces the disadvantage of a more costly simulation;¹³ this is particularly

true when a large set of solvent molecules must be included in the system to account for bulk solvation effects. To overcome this problem, continuum solvation models^{14–17} (CSMs) can be effectively used; in fact, different combinations of standard nonpolarizable FF and CSMs are available in various MD softwares. The mixed strategy is advantageous, with respect to a fully atomistic one, because the continuum easily takes into account the long-range interactions that would require a huge number of solvent molecules, increasing significantly the computational cost of the simulation, and implicitly includes the statistical average of their configurations. However, until

Received: November 7, 2014

now, the coupling between polarizable force fields and polarizable continuum models has been mostly used to obtain an alternative approach to the Periodic Boundary Conditions and a simplified spherical model has been used to represent the boundary between the atomistic and the continuum model. A notable example is the Generalized Solvent Boundary Potential (GSBP) approach developed by Roux and co-workers;¹⁸ however, approaches based on apparent surface charge (ASC) methods also have been presented.^{19–23} Alternatively, the coupling between PFFs and continuum models have been proposed for simplified versions of CSMs in which the atomistic part of the system can be polarized by the continuum part but not vice versa;²⁴ the Generalized Born Model²⁵ (GBM) is the typical continuum approach used, even if, more recently, a Generalized Kirkwood model²⁶ and a linearized Poisson–Boltzmann model²⁷ have been presented in combination with the AMOEBA polarizable force field.^{28,29}

To get a more realistic description of the environment effects, it would be important to have a fully polarizable scheme in which the two subsystems mutually polarize in a self-consistent way. This characteristic is one of the main reasons for the success of CSMs when coupled to quantum-mechanical descriptions.^{14,30} In fact, the QM electronic density is self-consistently adapted to the solvent polarization in QM/CSM formulations, and this allows us to account for the important effects that the solvent can have on molecular properties and processes of solvated systems. Therefore, we can expect that the same important effects can be seen in the classical simulation of processes when a polarizable description is used for the atomistic part of the system. Unfortunately, it is not straightforward to extend the CSMs that have been optimized for the coupling with a QM description, to classical and polarizable descriptions. In the QM cases, in fact, the cost of the overall calculation is largely dominated by the QM step; therefore, the computational effectiveness of the polarizable CSMs is not a real issue. When the polarizable CSM must be coupled to classical descriptions, instead, the picture can be completely reverted and the resolution of the self-consistent scheme, which determines the response of the CSM to the atomistic but classical subsystem, can become so severe that a bottleneck forms, making the entire approach practically useless when applied to MD simulations.^{31,32} Therefore, to have a really usable fully polarizable MM/CSM approach, the continuum approach must be reformulated in a very efficient way.

In this paper, we present the first scalable formulation of a fully polarizable MM/CSM that can be used in MD simulations of systems of real (bio)chemical interest. This formulation is achieved by coupling PFFs with the continuum model that we have recently proposed: the domain decomposition Conductor-like Screening Model (ddCOSMO).^{33–36} The latter is a continuum model that represents the polarization of the solvent in terms of a response limited to the surface of the molecular cavity embedding the atomistic subsystem (which can be treated either classically or quantum-mechanically). The ddCOSMO is characterized by linear scaling properties, with respect to the size of the system, and is well-suited for parallel implementations. Its capabilities were recently demonstrated for QM methods, enabling the optimization of large molecules in solvent with gain of up to 3 orders of magnitude in time, with respect to other CSMs.³⁵ Here, we propose a totally new implementation of the method, in combination with different

PFFs, based on induced dipoles, including variational and nonvariational PFFs.

The paper is organized as follows. In section 2, theory and algorithms are presented, with a special focus on the coupling issue in the framework of both variational and nonvariational PFFs. In section 3, the numerical stability of the simulations is demonstrated and an application to the simulation of solvent effects on the IR spectrum of a small polypeptide system is reported. Some conclusions and perspectives end the paper in section 4.

2. THEORY

In this section, we briefly recap the polarization equations for both point-dipole-based^{37,38} PFFs and the COSMO solvation model,³⁹ accordingly to the ddCOSMO discretization; we focus on the coupling of such models and discuss the special case of nonvariational force fields.²⁸ The algorithm implemented to solve the final, coupled equations is also briefly presented.

In a dipole-based PFF, the electrostatics of each atom i is described through a set of static multipoles and a polarizability α_i , which is a three-dimensional (3D) rank 2 symmetric tensor that describes the linear response of such an atom to a polarizing electric field \vec{E}_i . The static multipoles are usually point charges, but more advanced force fields can include higher-order multipoles, such as dipoles and quadrupoles; nevertheless, the field created by the multipolar distribution induces, at each polarizable site i , a point dipole $\vec{\mu}_i$, such that the interaction between the inducing field \vec{E}_i and the induced dipoles is maximized, while the work to induce the dipoles and the interaction between the induced dipoles are minimized. In a recent paper,¹³ we have thoroughly analyzed the properties of the polarization equations and we have introduced a Jacobi-DIIS scheme that has been shown to be robust, enjoy fast convergence properties, and be suitable for parallel implementations due to low communications between processes. All the details of the derivation can be found in ref 13. Here, it is sufficient to say that the induced dipoles are the minimizers of the following energy functional:

$$\mathcal{E} = -\sum_{i=1}^N E_i^\alpha \mu_i^\alpha + \frac{1}{2} \sum_{i=1}^M [\alpha_i^{-1}]^{\alpha\beta} \mu_i^\alpha \mu_i^\beta + \frac{1}{2} \sum_{i=1}^M \sum_{j \neq i}^M \mathcal{T}_{ij}^{\alpha\beta} \mu_i^\alpha \mu_j^\beta \quad (1)$$

where E_i^α is the α th component of the inducing field \vec{E}_i and μ_i^α is the α th component of the induced dipole $\vec{\mu}_i$, both at the polarization site i . The Latin indexes shown in the summations run over the M polarization sites, and the Greek indexes shown in the summations run over the Cartesian coordinates of the various quantities. For the latter indexes, Einstein summation is used.

$\mathcal{T}_{ij}^{\alpha\beta}$ describes the dipole–dipole interaction matrix:

$$\mathcal{T}_{ij}^{\alpha\beta} = -\frac{\delta_{\alpha\beta}}{r_{ij}^3} \lambda_3(u_{ij}) + 3 \frac{r_{ij}^\alpha r_{ij}^\beta}{r_{ij}^5} \lambda_5(u_{ij}) \quad (2)$$

where $\delta_{\alpha\beta}$ is the Kronecker symbol, r_{ij} is the distance between site i and site j ($r_{ij} = |\mathbf{r}_j - \mathbf{r}_i|$), and u_{ij} is the effective distance as a function of the averaged polarizabilities of sites i and j ($u_{ij} = r_{ij}/(\langle\alpha_i\rangle\langle\alpha_j\rangle)^{1/6}$), and $\langle\alpha_i\rangle = 1/3 \text{ tr}(\alpha_i)$. Such a matrix includes Thole's damping through the functions

$$\lambda_3(u) = 1 - e^{-au^3} \quad (3)$$

$$\lambda_5(u) = 1 - (1 + au^3)e^{-au^3} \quad (4)$$

Other functional forms are used in the literature for the damping functions; a detailed analysis can be found in refs 40 and 41. It is possible to introduce a more-compact notation by introducing a $3M$ -dimensional symmetric matrix \mathbf{T} , which we will refer to as the polarization matrix, and the $3M$ -dimensional fields and dipoles vectors, according to

$$\mathbf{T} = \begin{pmatrix} \alpha_1^{-1} & \mathcal{T}_{12} & \mathcal{T}_{12} & \dots & \mathcal{T}_{1M} \\ \mathcal{T}_{21} & \alpha_2^{-1} & \mathcal{T}_{23} & \dots & \mathcal{T}_{2M} \\ \mathcal{T}_{31} & \mathcal{T}_{32} & \ddots & & \\ \vdots & \vdots & & & \vdots \\ \mathcal{T}_{M1} & \mathcal{T}_{M2} & \dots & \alpha_M^{-1} \end{pmatrix},$$

$$\mathbf{E} = \begin{pmatrix} \vec{E}_1 \\ \vec{E}_2 \\ \vdots \\ \vec{E}_M \end{pmatrix}, \quad \boldsymbol{\mu} = \begin{pmatrix} \vec{\mu}_1 \\ \vec{\mu}_2 \\ \vdots \\ \vec{\mu}_M \end{pmatrix} \quad (5)$$

where the $\mathcal{T}_{ij} \in \mathbb{R}^{3 \times 3}$ blocks are those defined in eq 2. The energy functional defined in eq 1 becomes

$$\varepsilon = \frac{1}{2} \boldsymbol{\mu}^\dagger \mathbf{T} \boldsymbol{\mu} - \mathbf{E}^\dagger \boldsymbol{\mu} \quad (6)$$

Finally, the minimum condition leads to the following linear system:

$$\mathbf{T} \boldsymbol{\mu} = \mathbf{E} \quad (7)$$

CSMs require one to solve or approximate a partial differential equation (PDE) that, for polarizable models, is either the Poisson equation or the Poisson–Boltzmann equation. In particular, in the COSMO model, the solvent is represented as an infinite, uniform conductor that occupies the entire space but a cavity that accommodates the solute. There are several definitions for such a cavity,¹⁴ the most common being the van der Waals cavity, the solvent-accessible surface (SAS), and the solvent-excluded surface (SES): in the present work, we use a scaled van der Waals cavity, which we obtain as the union of interlocking spheres, one per atom, the radii of which are the van der Waals radii of the atoms scaled with a constant factor of 1.1. In the ddCOSMO framework, an iterative procedure based on Schwarz's domain decomposition method is used together with a discretization scheme based on spherical harmonics, which corresponds to solving a non-symmetric linear system:³³

$$LX = g_0 \quad (8)$$

where L is the ddCOSMO matrix, X is the unknown used to represent the solvent polarization, and g_0 is the solute's potential (weighted with suitable switching factors). More details can be found in refs 33 and 34, and in Appendix A. The ddCOSMO matrix is formed by M^2 blocks, each block corresponding to a sphere (and, hence, to an atom) and being sized $(N + 1)^2$, where N is the maximum angular momentum used for the spherical harmonics expansion of the

solution. Such a matrix is sparse, as only intersecting spheres are interacting, with any off-diagonal block corresponding to two spheres that do not intersect being zero. The ddCOSMO reaction energy, i.e., the electrostatic contribution to the solvation energy, is computed as

$$E_s = \frac{1}{2} f(\varepsilon) \langle \Psi_0, X \rangle \quad (9)$$

where $f(\varepsilon)$ is an empirical scaling that is introduced to account for the dielectric nature of the solvent³⁹ (typically, $f(\varepsilon) = (\varepsilon - 1)/\varepsilon$, where ε is the macroscopic dielectric constant of the solvent, and Ψ is a vector containing the solute's (static) multipolar distribution scaled with suitable factors and we have introduced the notation

$$\langle a, b \rangle = \sum_{j=1}^M \sum_{l=0}^N \sum_{m=-l}^l [a_j]_l^m [b_j]_l^m \quad (10)$$

The coupling of a dipole-based PFF and ddCOSMO can be obtained through a variational formulation.^{13,20,31} Given the ddCOSMO equations, it is in fact possible to write an energy functional that is variational with respect to the dipoles and includes mutual polarization between the dipoles and the continuum. Such a functional is the sum of the dipoles functional, as in eq 6, and the ddCOSMO energy:

$$\mathcal{G}(\boldsymbol{\mu}) = \frac{1}{2} \boldsymbol{\mu}^\dagger \mathbf{T} \boldsymbol{\mu} - \boldsymbol{\mu}^\dagger \mathbf{E}_0 + \frac{1}{2} f(\varepsilon) \langle \Psi, X \rangle \quad (11)$$

where

$$X = L^{-1} g \quad (12)$$

according to the ddCOSMO equation. Notice that we have introduced, for ddCOSMO, the quantities g and Ψ :

$$g = g(\boldsymbol{\mu}) = g_0 + g_\mu$$

$$\Psi = \Psi(\boldsymbol{\mu}) = \Psi_0 + \Psi_\mu \quad (13)$$

Such quantities are affine functions of $\boldsymbol{\mu}$ and correspond to the potential generated by the solute, including the induced dipoles, and to the scaled multipoles and induced dipoles (see eq A14 in the Appendix), respectively, and account for the interaction between the solute and the solvent. Notice that, since g_μ and Ψ_μ are linear in $\boldsymbol{\mu}$, we can write

$$g_\mu = B^* \boldsymbol{\mu}$$

$$\Psi_\mu = A^* \boldsymbol{\mu} \quad (14)$$

The ddCOSMO term in eq 11 introduces a combination of constant, linear, and quadratic terms, with respect to the induced dipoles, correctly implying the mutual polarization of the dipoles with the continuum, since the dipoles and ddCOSMO equations will be coupled. The coupled equations can be derived by imposing the stationarity of the new energy functional, with respect to the induced dipoles:

$$\frac{\partial \mathcal{G}}{\partial \boldsymbol{\mu}} = \mathbf{T} \boldsymbol{\mu} - \mathbf{E}_0 + \mathbf{E}_c = 0 \quad (15)$$

where we have introduced the COSMO field \mathbf{E}_c , which is obtained by differentiating the COSMO energy, with respect to the induced dipoles:

$$\begin{aligned} \mathbf{E}_c &= \frac{1}{2}f(\varepsilon)\frac{\partial}{\partial\mu}\langle\Psi, X\rangle \\ &= \frac{1}{2}f(\varepsilon)\left[\left\langle\frac{\partial\Psi}{\partial\mu}, X\right\rangle + \left\langle\Psi, \frac{\partial X}{\partial\mu}\right\rangle\right] \end{aligned} \quad (16)$$

Both terms of eq 16 are obtained with a linear transformation of either the ddCOSMO solution X or the solution to the ddCOSMO adjoint equations $L^*S = \Psi$; in particular,

$$\mathbf{E}_c = \frac{1}{2}f(\varepsilon)[AX + BS] \quad (17)$$

The expressions that define matrices A and B , together with the derivation of eqs 17 and 14, can be found in Appendix B. We are now ready to write the coupled equations for the dipoles and the continuum. By putting everything together, eq 15 becomes

$$\mathbf{T}\mu + \frac{1}{2}f(\varepsilon)AX + \frac{1}{2}f(\varepsilon)BS = \mathbf{E}_0 \quad (18)$$

where the direct and adjoint ddCOSMO equations, which we need to compute X and S , are

$$LX = g = g_0 + B^*\mu \quad (19)$$

and

$$L^*S = \Psi = \Psi_0 + A^*\mu \quad (20)$$

We can put everything together into a global linear system:

$$\begin{pmatrix} \mathbf{T} & \frac{1}{2}f(\varepsilon)A & \frac{1}{2}f(\varepsilon)B \\ -B^* & L & 0 \\ -A^* & 0 & L^* \end{pmatrix} \begin{pmatrix} \mu \\ X \\ S \end{pmatrix} = \begin{pmatrix} \mathbf{E}_0 \\ g_0 \\ \Psi_0 \end{pmatrix} \quad (21)$$

Once the linear system in eq 21 has been solved, the total polarization energy (i.e., including both the dipoles polarization and the continuum polarization) is computed according to eq 11.

2.1. A Special Case: Nonvariational Force Fields. In the previous derivation, we assumed that the polarization energy is a variational functional of the induced dipoles. This assumption is not respected in the AMOEBA force field,^{28,29} where the polarization energy is computed as the electrostatic interaction between the induced dipoles, computed according to eq 7 (and, therefore, as the solution to a variational problem), and an electric field that is different from the inducing one. The two fields differ for the local interaction scaling: while the inducing field (usually called “direct field”, E_d) at polarization site i is the field produced by all the multipoles on all the other sites, the contributions to the interacting field (usually called “polarization field”, E_p) from the closest neighbors (i.e., 1–2, 1–3, and 1–4) are scaled in order to take into account that the interaction energy between such atoms is usually taken into account by using the bonding terms. To summarize, the AMOEBA polarization energy is defined as follows:

$$E_A = -\frac{1}{2}(\mu_d)^\dagger \mathbf{E}_p \quad (22)$$

where the “direct” dipoles are the solution to the polarization equations, as given in eq 7:

$$\mathbf{T}\mu_d = \mathbf{E}_d$$

In order to couple the AMOEBA force field with ddCOSMO, it is possible to manipulate the AMOEBA polarization energy in order to write it as a combination of variational terms. Let μ_p be the solution to

$$\mathbf{T}\mu_p = \mathbf{E}_p$$

According to our derivation, the “p” dipoles will be the minimizers of

$$\mathcal{E}(\mu_p) = \frac{1}{2}(\mu_p)^\dagger \mathbf{T}\mu_p - (\mu_p)^\dagger \mathbf{E}_p$$

It is easily shown that

$$E_A = \frac{1}{2}(\mu_d)^\dagger \mathbf{E}_p = \mathcal{E}(\mu_d + \mu_p) - \mathcal{E}(\mu_d) - \mathcal{E}(\mu_p) \quad (23)$$

where the two sets of dipoles are the variational minimizers of the associated energy functional. Therefore, the AMOEBA polarization energy can be expressed as the combination of three variational expressions. We proceed to couple ddCOSMO to the AMOEBA force field by replacing each term in eq 23 with the corresponding “solvated” energy functional, described by eq 11:

$$G_A := \mathcal{G}(\mu_d + \mu_p) - \mathcal{G}(\mu_d) - \mathcal{G}(\mu_p) \quad (24)$$

Here, both sets of dipoles are determined by minimizing the associated \mathcal{G} functional, i.e., by solving the coupled linear system in eq 21 for two different right-hand sides:

$$\begin{pmatrix} \mathbf{T} & \frac{1}{2}f(\varepsilon)A & \frac{1}{2}f(\varepsilon)B \\ -B^* & L & 0 \\ -A^* & 0 & L^* \end{pmatrix} \begin{pmatrix} \mu_d \\ X_d \\ S_d \end{pmatrix} = \begin{pmatrix} \mathbf{E}_d \\ g_0 \\ \Psi_0 \end{pmatrix} \quad (25)$$

and

$$\begin{pmatrix} \mathbf{T} & \frac{1}{2}f(\varepsilon)A & \frac{1}{2}f(\varepsilon)B \\ -B^* & L & 0 \\ -A^* & 0 & L^* \end{pmatrix} \begin{pmatrix} \mu_p \\ X_p \\ S_p \end{pmatrix} = \begin{pmatrix} \mathbf{E}_p \\ g_0 \\ \Psi_0 \end{pmatrix} \quad (26)$$

The AMOEBA/ddCOSMO energy expression can be simplified by substituting the explicit expression of the various functionals: through some trivial, but cumbersome algebra, we get

$$\begin{aligned} G_A &= \frac{1}{2}(\mu_d)^\dagger \mathbf{T}\mu_p - \frac{1}{2}\mu_d^\dagger \mathbf{E}_p - \frac{1}{2}\mu_p^\dagger \mathbf{E}_d \\ &\quad + \frac{1}{4}f(\varepsilon)[\langle\Psi_p, X_d\rangle + \langle\Psi_d, X_p\rangle] \end{aligned} \quad (27)$$

where we have introduced the short notations $\Psi_d = \Psi_0 + \Psi_{\mu_d}$ and $\Psi_p = \Psi_0 + \Psi_{\mu_p}$.

2.2. Analytical Derivatives of the Polarization Energy.

Analytical derivatives can be easily assembled by differentiating eq 11, remembering that, having solved the coupled polarization equations, such a functional is stationary, with respect to the dipoles:¹³

$$\mathcal{G}^x = \frac{\partial\mathcal{G}}{\partial x} + \frac{\partial\mathcal{G}}{\partial\mu} \frac{\partial\mu}{\partial x} \quad (28)$$

where x denotes a generic coordinate of an atom.

In the variational case, the last term in eq 28 vanishes and the derivatives of the dipoles do not need to be assembled. By expanding eq 28, we get

$$\mathcal{G}^x = \frac{1}{2} \boldsymbol{\mu}^\dagger \mathbf{T}^x \boldsymbol{\mu} - \boldsymbol{\mu}^\dagger \mathbf{E}_0^x + \frac{1}{2} f(\epsilon) (\langle \Psi^x, X \rangle + \langle \Psi, X^x \rangle) \quad (29)$$

The derivatives of the matrix \mathbf{T} and of the electric field have been discussed extensively in ref 13. The derivatives of the Ψ vector are nonzero only if the solute's multipolar distribution contains static multipoles of angular momentum greater than zero, i.e., dipoles, quadrupoles, and higher-order terms: such multipoles are, in fact, vector or tensor quantities, which must be defined in a local framework and rotated in the laboratory framework: such a transformation is dependent on the position of the atoms and contributes to the total derivatives. These contributions have also been extensively discussed in ref 13. The derivatives of the X expansion coefficients can be computed by differentiating the ddCOSMO equations:

$$L^x X + L X^x = g^x \Rightarrow X^x = L^{-1}(g^x - L^x X) \quad (30)$$

By substituting into the last term of eq 29, the following expression is obtained:

$$\langle \Psi, X^x \rangle = \langle \Psi, L^{-1}(g^x - L^x X) \rangle = \langle S, g^x - L^x X \rangle \quad (31)$$

Notice that the solution to the adjoint system is already available, because it is necessary to compute it in order to solve the coupled linear system. A complete derivation of the ddCOSMO analytical derivatives, including the expressions of g^x and L^x can be found in ref 34.

Analytical derivatives for the nonvariational case can be formulated using the same procedure elucidated in the previous section, i.e., by writing the energy as a combination of variational contributions, differentiating each variational contribution and putting everything together. Through some algebra, we get

$$\begin{aligned} G_A^x = & \frac{1}{2} \mu_p^\dagger \mathbf{T}_d^x \mu_d - \frac{1}{2} \mu_p^\dagger \mathbf{E}_d^x - \frac{1}{2} \mu_d^\dagger \mathbf{E}_p^x \\ & + \frac{1}{4} f(\epsilon) [\langle \Psi_d^x, X_p \rangle + \langle \Psi_d, X_p^x \rangle + \langle \Psi_p^x, X_d \rangle + \langle \Psi_p, X_d^x \rangle] \end{aligned} \quad (32)$$

2.3. Implementation Details. The solution to the coupled polarization equations is a computationally demanding task, since the size of the linear system can easily become very large. Direct techniques, such as LU decomposition, cannot be employed, because, even for medium-sized systems, the matrix in eq 21 can be too large to be stored in memory. Fortunately, the sparsity of the ddCOSMO matrix allows for a very efficient, linear-scaling iterative procedure to solve the direct and adjoint ddCOSMO equations: such an iterative procedure can be coupled with an iterative solver for the dipoles linear system. In particular, we use Jacobi Iterations (JIs) coupled with the Direct Inversion in the Iterative Subspace (DIIS) extrapolation both for ddCOSMO³⁴ and for the dipoles.¹³ The details of the implementation and a thorough analysis of the various possible algorithm to treat the polarization equations can be found elsewhere.^{13,42} Three families of iterative strategies are possible, in principle, to solve the coupled equations:

- the first is the so-called monolithic approach, i.e., to address the full linear system at once through an iterative procedure;
- the second is to iterate on the dipoles (macroiterations) and, at each macroiteration, fully solve the ddCOSMO direct and adjoint equations (microiterations); and
- the third is to iterate on the ddCOSMO direct and adjoint equations (macroiterations) fully solving, at each macroiteration, the dipoles system (microiterations).

Various refinements, such as doing an adaptive number of macroiteration, depending on the convergence, or using a varying threshold for the microiterations, depending on the convergence of the macroiterations, can be adopted to accelerate the process. The three strategies have been implemented and explored: the second and third ones resulted in being the most competitive. Nevertheless, in the perspective of performing MD simulations, the ability of providing a very good guess for the dipoles led us to adopt the second strategy, which we will now detail.

Initial Computation and Guess. The first step of the computation is to assemble the right-hand side of eq 21, that is, the electric field of the solute at the polarizable sites, its potential at the cavity, and the Ψ_0 vector, which is formed by scaling the solute multipolar distribution according to eq A14 in Appendix A. A guess is also formed for the dipoles: in a previous paper,¹³ we analyzed various possibilities and found that using the predictor step of Kolafa's integrator⁴³ as a guess provided a very effective form of convergence acceleration. Kolafa's guess requires one to know the solution at the six previous points: for the first six steps in a MD simulation, we use what we called in the previous paper the direct field guess, i.e., we initialize the dipoles to

$$\vec{\mu}_i = \alpha_i \vec{E}_i^0$$

Both the ddCOSMO X and S coefficients are initialized to zero. Given the guessed dipoles, the total potential Φ and the total Ψ vector are assembled.

Main Loop. The main iteration loop starts with two calls to the ddCOSMO iterative solver: for the direct and adjoint systems, respectively. Such calls are completely independent and can be run in parallel. The ddCOSMO linear systems are solved iteratively by Jacobi/DIIS using a variable convergence threshold; in particular, we start with a threshold of 10^{-3} and, along the macroiterations, we set it to one-tenth of the root-mean-square (RMS) increment on the dipoles. Also, at macroiteration i , we use $X^{[i-1]}$ and $S^{[i-1]}$ as guesses. Once the two ddCOSMO linear systems have been solved, the COSMO electric field is computed, according to eq 17 and added to the E_0 field. A Jacobi step is then performed on the dipoles and the RMS of the increment and its maximum are computed. Convergence is achieved when the RMS is smaller than a threshold provided by the user and the maximum is 10 times smaller than such a threshold. If convergence has not been reached, the DIIS extrapolation is carried out on the dipoles. Finally, the total potential and Ψ vector are updated for the following iteration. Notice that, for the nonvariational case, two sets of dipoles (and, hence, of ddCOSMO coefficients) are addressed; nevertheless, the matrix is formed on the fly and multiplied by both sets of dipoles, with limited—but not negligible—computational overhead. This step is the most time-consuming, as several matrix-vector products are to be evaluated.

Energy and Forces. Once the coupled equations have been solved, we proceed to compute the solvation and polarization energy, according to eq 11 or eq 27 in the nonvariational case.

Table 1. Stability of NVE Simulations, as a Function of the Convergence Threshold for the Coupled Polarization Equations and of the Time Step (AMBER/Wang Variational Force Field)^a

^aFor each combination, the short-time average fluctuation (STF), the long-time drift (LTD), and the average computational time per time step (ACT) are reported. All the energies are given in terms of kcal/mol, all timings are given in seconds.

The forces are then computed according to eq 28, or eq 32, in order to be used for the integration of the equations of motion in the MD simulation.

This strategy has been implemented in the Tinker Package and parallelized according to either the OpenMP or the MPI paradigms. The implementation of the ddCOSMO field has been checked by comparing the computed field with that obtained by numerically differentiating the energy with respect to the dipoles; the same validation has been carried out with the forces, which have been compared with numerical derivatives of the energy with respect to the positions of the nuclei. In both cases, an agreement up to numerical precision was observed; also, the forces rigorously sum to zero, independent of the discretization and of the convergence threshold used.

3. RESULTS

3.1. Numerical Tests. In this section, we will analyze the behavior of a MD simulation performed with a PFF coupled to ddCOSMO, with respect to the convergence used for the linear equations and to the time step used in the MD. We will also comment on the timings and on the performances of our code on parallel architectures.

Computational Details. All the computations have been performed with a locally modified module of the TINKER⁴⁴ package, called Tinker-HP, which was dedicated to parallel implementations. The iterative solver used for the polarization equations and the ddCOSMO algorithm were implemented in such a module and parallelized according to either the OpenMP or MPI paradigms. As a test case, we performed a 100-ps NVE MD simulation on a small protein (Protein DataBank (PDB) reference code 1FSV), using increasing convergence thresholds and timesteps. The PDB structure was minimized with analytical gradients, and a 20-ps NVT equilibration was performed using the Berendsen Thermostat⁴⁵ in order to provide a starting point for the NVE simulations. Both a variational force field (namely, the AMBER ff99 force field with the parametrization of Wang et al.^{40,46} for the polarizable electrostatics) and a nonvariational one (namely, the AMOEBA99bio²⁸ force field) were employed. All the computations were performed on a dual Xeon Model E5-2650

cluster node (16 cores, 2 GHz) equipped with 64GB of DDR3 memory.

For each simulation, we report (i) the short time average fluctuation, which we compute by averaging the RMS fluctuations of the energy computed every 100 steps; (ii) the long-range energy drift, which we compute by fitting the total energy as a function of time with a linear function

$$E(t) = at + b$$

and by computing the value of such a function at 100 ps; and (iii) the average computational time per time step, which we compute as the total computational time over the number of time steps. The results are summarized in Table 1 for the AMBER/Wang variational force field and in Table 2 for the AMOEBA force field. From the results reported in Tables 1 and 2, we can infer the good stability of the polarizable dynamics. Short-time fluctuations are always <1 kcal/mol, even using the sleaziest convergence threshold and the longer time step, for both the variational and the nonvariational force field. This proves the good quality of the computed forces, which not only sum rigorously to zero (i.e., the total momentum is conserved), but are also little sensitive to the small error on the dipoles and ddCOSMO equations solution due to a non-fully converged iterative procedure. Furthermore, such a drift shows little or no dependence on the threshold and a test performed with very tight convergence does not show further improvements: therefore, the short-term fluctuations are mainly a consequence of the Velocity Verlet integrator. Notice how the STF illustrates that such an integration scheme is second order in the time step. Long-term stability is more subtle to analyze, since it is the result of several interacting causes. The Velocity Verlet is a second-order symplectic integrator and its time reversibility grants, in exact precision, the long-term stability of the simulation; however, round-off errors and a nonperfect convergence of the polarization degrees of freedom can spoil energy conservation, producing a drift. Furthermore, the guess for the iterative solution can break the overall time reversibility of the simulation, either being itself non-time-reversible (for instance, using the solution at the previous step produces a nonsymmetric expression, with respect to time inversion) or being time-reversible only for fully converged solutions and

infinite precision. The latter is the case for our choice of a guess: as mentioned in section 2.3, we use the prediction step of Kolafa's predictor corrector, the reversibility of which, when used as a guess, is spoiled by convergence and round-off errors. Such effect is more marked for longer time steps and sleazier convergence thresholds, producing a drift that can be as large as 20 kcal/mol per 100 ps. This analysis is further complicated by the interaction of the various sources of long-time effects, which can produce error cancellation: this explains, for instance, the nonsystematic behavior that we observed (for instance, for the AMOEBA simulation, where, for a convergence threshold fixed to 10^{-4} , the 1 fs time-step simulation is more stable than the 0.5 fs time-step simulation).

Nevertheless, our results show that it is indeed possible to perform a stable MD simulation with a PFF coupled to a polarizable continuum by choosing an appropriate combination of time step and convergence thresholds. We also remark that, thanks to the excellent short-time behavior, it is possible to correct the long-time behavior by using a thermostat: even the 1-fs step- 10^{-4} threshold can be used with a noticeable savings in computational time. We stress that Kolafa's predictor, as shown in a recent publication,¹³ is a very effective guess, which greatly reduces the number of iterations needed to converge the polarization equations: the small instabilities introduced are a price worth paying for the computational savings produced.

We conclude this section by discussing briefly the MPI parallel implementation of our procedure. For the ddCOSMO solver, which needs to be called twice per iteration, a spacial decomposition load balancing strategy is used to ensure that each process is given a similar workload; moreover, non-blocking communication is used to mask the communication overhead. Once the two ddCOSMO linear system have been solved, the solutions are broadcast to all the processes in order to compute the COSMO field and the next iteration dipoles are computed. These, in turn, are broadcast in order to compute the potential and vector Ψ for the next ddCOSMO computation. The overall scaling properties of the algorithm for a system composed of $\sim 10\,000$ atoms are reported in Figure 1. While the scaling deviates from the ideal one, the overall performances of the code are quite good and allow one to use our implementation on parallel computers. It appears that the ddCOSMO solver is the limiting component, in terms

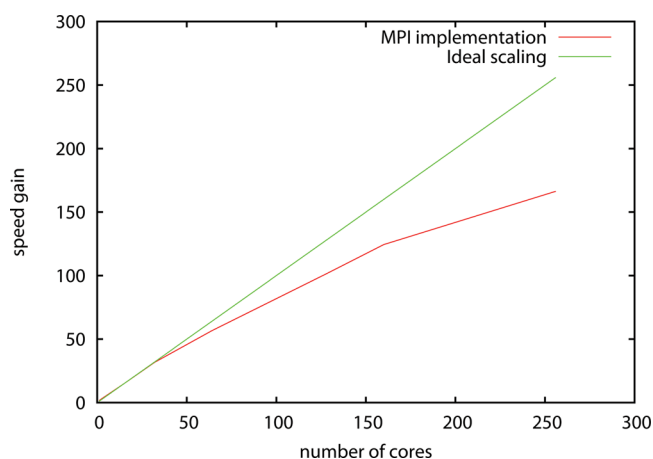

Figure 1. Scaling of the MPI code for the coupled induced dipoles/ddCOSMO problem, with respect to a single-node (16 cores) computation.

of parallel scaling; furthermore, while a hybrid OpenMP/MPI implementation showed very promising results for the direct-space solution of the polarization equations, this was not the case for the ddCOSMO equations and, therefore, for the coupled PFF/ddCOSMO ones. A more efficient parallel implementation is under active investigation.

3.2. Solvatochromism of an α -Helical Polypeptide. In order to test the ability of ddCOSMO to introduce solvation effects in a MD simulation, we have studied the solvatochromism of a model peptide in its α -helix secondary structure. MD simulations have been performed by using a development version of the Tinker program⁴⁴ and the AMOEBA99bio force field.²⁸ The system consists of a single α -helical polypeptide composed of 20 amino acids. To consider the solvatochromism, two sets of five trajectories have been considered, both in vacuo and in water, by means of the ddCOSMO implicit scheme described in this paper. For both sets of trajectories, a first set of simulations of 20 ps were performed in the canonical (NVT) ensemble at room temperature to ensure the thermalization step, using a Berendsen thermostat;⁴⁵ subsequent trajectories of 20 ps in the microcanonical ensemble (NVE) for production have been computed. Equations of motion have been integrated with the Velocity Verlet scheme⁴⁷ and a time step of 0.1 fs. IR spectra are obtained from the Fourier transform of the dipole autocorrelation function:⁴⁸

$$I(\omega) \propto \int_0^T \langle \mu(0)\mu(t) \rangle e^{-i\omega t} dt \quad (33)$$

where μ is the molecular dipole and T is the simulation time. The assignment of vibrational bands in terms of atomic displacements can be achieved through vibrational density of states, calculated as the Fourier transform of the velocity correlation function:

$$P(\omega) = \sum_{j=1}^M \int_0^T \langle v_j(0) \cdot v_j(t) \rangle e^{-i\omega t} dt \quad (34)$$

where v_j is the velocity of atom j . We then projected the velocity autocorrelation function on internal coordinates or selected atoms (C and O atoms of amide in our cases) for a more comprehensive assignment of the peaks.⁴⁸

Computed IR spectra (black lines) and vibrational densities of states projected on the C and O atoms of all amide groups (blue lines) for the α -helix model are shown in Figures 2 and 3

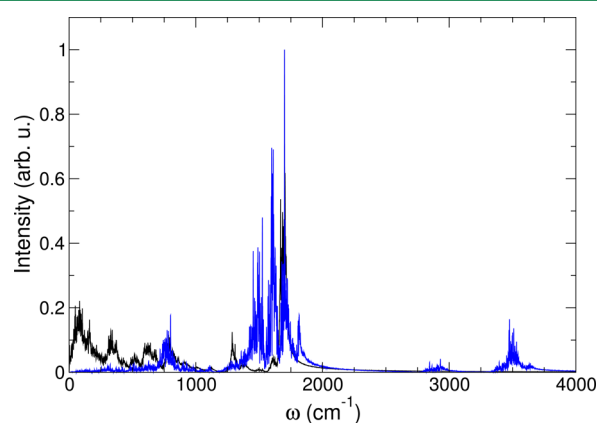

Figure 2. Computed IR spectra (black) and projected vibrational density of states (blue) on C and O atoms of all amide groups for an α -helix polypeptide model *in vacuo*.

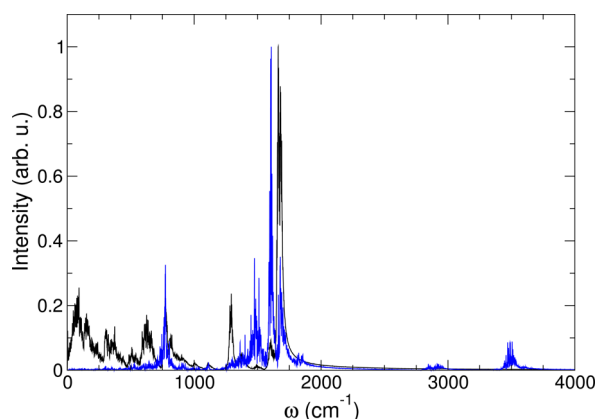

Figure 3. Computed IR spectra (black) and projected vibrational density of states (blue) on C and O atoms of all amide groups for an α -helix polypeptide model in water.

for the *in vacuo* and in water computations, respectively. Assignments of the active IR bands corresponding to the amide I region can be easily achieved through the vibrational density of states projected on C and O atoms of all amide groups (blue lines): the bands of the IR spectrum with maximal overlap with the main bands of the power spectrum are assigned to the motion of the C and O atoms of the amide groups.

Indeed, the amide I mode frequency is found to be 1700 cm^{-1} *in vacuo* and $1665\text{--}1680\text{ cm}^{-1}$ in water, which is in fair agreement with the expected range of frequencies of α -helix (1654 cm^{-1}). Moreover, the solvation-induced amide I mode frequency shift was found to be between -20 cm^{-1} and -35 cm^{-1} , which is in excellent agreement with previous classical MD simulations using an explicit treatment of the solvation of a α -helix model.⁴⁹ This result demonstrates the ability of the ddCOSMO scheme to correctly reproduce the solvatochromism of the amide I region for a α -helix model without the explicit treatment of solvent molecules.

4. CONCLUSIONS AND PERSPECTIVES

We have presented, for the first time, a formulation and implementation of polarizable MD in a polarizable continuum solvent without restrictions on the cavity shape and without approximations on the coupling between the polarization degrees of freedom. A solid variational formulation has been proposed to introduce the coupling and derive the equations; a generalization to nonvariational polarizable force fields has then been achieved by writing the nonvariational energy as a linear combination of variational functionals. Thanks to a new formulation for the continuum, ddCOSMO, it is indeed possible to solve the mutual polarization equations for both the continuum and the dipoles very efficiently; furthermore, the algorithm is highly suited for parallelization and a scalable implementation is already available. The combination of algorithmics, code optimization, and parallelization makes the method fully operational and not just a proof of concept: while being more expensive than standard ones, polarizable MD simulations in a polarizable continuum can be performed for medium-to-large systems, even on a single computer node in reasonable times (i.e., roughly one second per time step). Nevertheless, in order to apply this methodology to larger systems, the use of the MPI code on large computers becomes mandatory. Furthermore, the use of linear scaling techniques, such as the Fast Multipole Method, to overcome the quadratic

bottlenecks that are associated with the evaluation of the MM/Continuum couplings and of the induced dipoles iterations, will also make computations on larger systems possible.

Momentum and energy conservation have been rigorously assessed. The analytical forces always sum to zero, implying momentum conservation and very good behavior of NVE simulations, with respect to short-time fluctuations; long-time energy conservation can be obtained by combining the use of a tight convergence threshold for the polarization equations, an adequate time step, and a nonbiased guess for the dipoles. Nevertheless, the long-term stability remains acceptable, even for sleazy converge thresholds, long time steps, and a non-fully time-reversible guess for the dipoles: the small and slow long-term drift can be easily controlled by a weakly coupled thermostat. The capabilities of this new methodology have been sketched with a test-case application, where we succeeded in reproducing the solvatochromic shift of the amide I mode of an α -helix oligopeptide. We would like to note that we have obtained such a result without any reparametrization of either the force field (and, in particular, the electrostatic and van der Waals terms) or the continuum (in particular, the atomic radii used to define the cavity): more-accurate results can be easily obtained by a better tailoring of the method.

The ddCOSMO algorithm has been implemented for both standard and polarizable force fields in a new Tinker module implemented in our groups and devoted to massively parallel implementation; it will coexist with a parallel implementation of both the electrostatic and polarization energies and forces in the context of periodic boundary conditions simulations with the Particle Mesh Ewald approach.^{50,51}

While this article already proposes a fully operational strategy, many developments can be considered. From a methodological point of view, further investigations on the molecular cavity are needed, as the van der Waals cavity can be not completely satisfactory: artificial holes in the cavity, which expose the solute to the solvent in nonphysical regions, could be avoided by using a more-advanced definition of the cavity itself, such as the so-called solvent excluded surface. Also, nonequilibrium effects, which are due to retardation effects in the solvent response, are currently neglected: while the role of the continuum here is mainly to provide a suitable boundary for the simulation, such effects can be important and must be included in a complete model. From a computational point of view, several developments are possible. Because of the characteristics of the algorithm, a GPU implementation is particularly interesting and should produce noticeable performance gains. A possibility worthy of investigation would be to propagate the induced dipoles in a Car–Parrinello fashion; however, this would require a careful choice of the fictitious mass of the dipoles and could produce numerical instabilities or artifacts. Some coarse-graining of the cavity, for instance, by not endowing the hydrogen atoms with their own sphere, but including them in the sphere of the heavy atom to which they are attached, could also produce large performance gains without compromising the accuracy if the motion of an hydrogen atom is not the objective of the study. Further code optimization and parametrization, with particular focus on the nonelectrostatic terms for solvation, could then open the way to free-energy computations, with interesting applications in the field of biochemistry and pharmacology.

■ APPENDIX A: THE ddCOSMO DISCRETIZATION OF THE COSMO MODEL

The Conductor-like Screening Model (COSMO) is a polarizable continuum solvation model that models the solvent as a structureless, uniform continuum conductor. The solute is accommodated into a molecule-shaped cavity (Ω) and the interaction with the environment is described as the electrostatic interaction of the density of charge of the solute with the polarization field created by the conductor. Throughout this paper, we will assume that the molecular cavity is a scaled van der Waals cavity, built as the union of spheres centered at the atoms, with the van der Waals radius of the atom scaled by a factor of 1.1. This interaction energy is then scaled with an empirical factor $f(\epsilon)$, in order to account for the dielectric nature of the solvent. The polarization of the conductor is computed by numerically solving Poisson's equation, which is usually recast as an integral equation on the cavity boundary ($\Gamma = \partial\Omega$). Since a conductor has a constant, zero potential, the potential produced by the solute *in vacuo* (Φ) plus the potential due to the polarization W of the metal (the so-called *reaction potential*) must sum to zero at the boundary:

$$W(\mathbf{s}) + \Phi(\mathbf{s}) = 0 \quad \forall \mathbf{s} \in \Gamma$$

The reaction potential can be represented in terms of an apparent surface charge (ASC) σ induced at the boundary:

$$W(\mathbf{r}) = \int_{\Gamma} \frac{\sigma(\mathbf{s})}{|\mathbf{r} - \mathbf{s}|} d\mathbf{s} \quad \forall \mathbf{r} \in \Omega \cup \Gamma \quad (\text{A1})$$

By combining the two relations, one obtains the COSMO integral equation:

$$\int_{\Gamma} \frac{\sigma(\mathbf{s}')}{|\mathbf{s} - \mathbf{s}'|} d\mathbf{s}' = (S_{\Gamma}\sigma)(\mathbf{s}) = -\Phi(\mathbf{s}) \quad (\text{A2})$$

The solvation energy is then computed as

$$E_s = \frac{1}{2}f(\epsilon) \int_{\Omega} \rho(\mathbf{r})W(\mathbf{r}) d\mathbf{r} = \frac{1}{2}f(\epsilon) \int_{\Gamma} \Phi(\mathbf{s})\sigma(\mathbf{s}) d\mathbf{s} \quad (\text{A3})$$

where ρ is the solute's density of charge, $f(\epsilon)$ is the scaling factor ($f(\epsilon) = (\epsilon - 1)/\epsilon$), ϵ is the dielectric constant of the solvent, and the factor $1/2$ takes into account the work needed to polarize the conductor. The COSMO equation is usually discretized using the Boundary Element Method (BEM), which transforms the integral equation into a dense linear system that can be solved iteratively; as the matrix-vector products implied in the iterative solution, corresponding to computing the potential produced by a given set of charges, the Fast Multipole Method (FMM) can be used to achieve linear scaling in computational cost. Nevertheless, solving the COSMO equation remains a demanding task, in terms of computational resources.

Recently, we have presented a new discretization for COSMO, based on Schwarz's Domain Decomposition method: we will refer to the new discretization as ddCOSMO. The ddCOSMO algorithm is an iterative procedure that decomposes the COSMO problem in the molecular cavity Ω to a collection of coupled problems in each of the spheres Ω_j that compose the cavity. At iteration it , for each sphere Ω_j , a COSMO-like integral equation is solved on its boundary ($\Gamma_j = \partial\Omega_j$):

$$(S_j\sigma_j^{(it)})(\mathbf{s}) = g(\mathbf{s}) \quad \forall \mathbf{s} \in \Gamma_j \quad (\text{A4})$$

The value of the term on the right-hand side (g) is dependent on whether point \mathbf{s} belongs to the global cavity's boundary (i.e., it is *exposed* to the solvent) or it is inside one or more other spheres (i.e., it is *buried* inside the cavity). If the point is exposed, the right-hand side is equal to minus the solute's electrostatic potential $\Phi(\mathbf{s})$; if the point is buried, i.e., if the point \mathbf{s} is inside some other sphere Ω_k , g is computed from the reaction potential inside Ω_k at the previous iteration, which, in turn, is computed from $\sigma_k^{(it-1)}$, according to eq A1, where $\sigma_k^{(it-1)}$ is the solution to the integral equation on sphere k at iteration $it - 1$. If point \mathbf{s} belongs to more than one sphere, g is computed as the average of the reaction potentials in each sphere to which point \mathbf{s} belongs. Let $N_j(\mathbf{s})$ be the list of spheres that intersect Ω_j at \mathbf{s} and let $|N_j(\mathbf{s})|$ be the number of such spheres. Let also χ_k be the characteristic function of Ω_k , i.e.,

$$\chi_k(\mathbf{r}) = \begin{cases} 1 & \text{if } \mathbf{r} \in \Omega_k \\ 0 & \text{otherwise} \end{cases}$$

A point $\mathbf{s} \in \Gamma_j$ is external if and only if the characteristic functions of all of the spheres Ω_k ($k \neq j$) are zero, i.e., if

$$\sum_{k \in N_j(\mathbf{s})} \frac{\chi_k(\mathbf{s})}{|N_j(\mathbf{s})|} = \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s}) = 0 \quad (\text{A5})$$

where, for later convenience, we have introduced the normalized weights $\omega_{jk}(\mathbf{s}) = (\chi_k(\mathbf{s}))/|N_j(\mathbf{s})|$ and we adopt the convention $0/0 = 0$. Note that, in practice, the functions χ_k must be smoothed out to obtain regular potential energy surfaces. This technical point is detailed in ref 34. We can now express the right-hand side of eq A4 as

$$g(\mathbf{s}) = -\left(1 - \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})\right)\Phi(\mathbf{s}) + \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})(S_k\sigma_k^{(it-1)})(\mathbf{s}) \quad \forall \mathbf{s} \in \Gamma_j \quad (\text{A6})$$

This leads, for each sphere j , to the following equation:

$$(S_j\sigma_j^{(it)})(\mathbf{s}) = -\left(1 - \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})\right)\Phi(\mathbf{s}) + \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})(S_k\sigma_k^{(it-1)})(\mathbf{s}) \quad \forall \mathbf{s} \in \Gamma_j \quad (\text{A7})$$

Notice how eq A7 represents a Jacobi iteration for a linear system of integral equations, which defines the COSMO model:

$$(S_j\sigma_j)(\mathbf{s}) - \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})(S_k\sigma_k)(\mathbf{s}) = -\left(1 - \sum_{k \in N_j(\mathbf{s})} \omega_{jk}(\mathbf{s})\right)\Phi(\mathbf{s}) \quad \forall \mathbf{s} \in \Gamma_j \quad (\text{A8})$$

The ddCOSMO system of integral equations is easily discretized in a real spherical harmonics basis through the following Ansatz:

$$\sigma_j(\mathbf{s}) = \sum_{lm} [X_j]_{lm}^m Y_l^m \left(\frac{\mathbf{s} - \mathbf{r}_j}{|\mathbf{s} - \mathbf{r}_j|} \right)$$

For each sphere, each operator in eq A8 (i.e., either the "diagonal" S_j or the "off-diagonal" S_{jk}) is represented by a

matrix L_{jj} (or L_{jk}), whose size is given by the number of spherical harmonics used for the discretization. Hence, the ddCOSMO global matrix L will be composed of $M \times M$ blocks of size $N_b \times N_b$, where $N_b = (L_{\max} + 1)^2$ and L_{\max} is the maximum angular momentum in the spherical harmonics basis.

The choice of real spherical harmonics is particularly advantageous, as the \mathcal{S} operator is diagonal in such a basis:

$$[L_{jj}]_{ll'}^{mm'} = \langle l, m | \mathcal{S} | l', m' \rangle = \frac{4\pi}{2l+1} \delta_{ll'} \delta_{mm'} \quad (\text{A9})$$

where we have used Dirac's notation and $|l, m\rangle$ represents the spherical harmonic of quantum numbers l, m . The discretization of the \mathcal{S}_{jk} operators is less straightforward, since it is not possible to compute the integrals analytically. However, an efficient numerical quadrature exists for the unit sphere: therefore, the numerical integration can be easily computed through the Lebedev rule. Let $\{\mathbf{y}_n, w_n\}_{n=1}^{N_s}$ be a set of Lebedev points and weights: the final expression for the off-diagonal blocks of the ddCOSMO matrix is

$$\begin{aligned} [L_{jk}]_{ll'}^{mm'} &= -\langle l, m | \omega_{jk} \mathcal{S}_k | l', m' \rangle \\ &= -\sum_{n=1}^{N_s} w_n Y_l^m(\mathbf{y}_n) W_n^{jk} \frac{4\pi}{2l'+1} (t_n^{jk})^{l'} Y_{l'}^{m'}(\mathbf{s}_n^{jk}) \end{aligned} \quad (\text{A10})$$

A complete derivation of eq A10 and all the details of the ddCOSMO method can be found in refs 33 and 34; here, note that the quantities t_n^{jk} , \mathbf{s}_n^{jk} , and W_n^{jk} are dependent only on the Lebedev grid and the geometry of the system. Moreover, the W_n^{jk} coefficient, which corresponds to $\omega_{jk}(\mathbf{y}_n)$ (defined in eq A5), vanishes if the spheres j and k do not intersect: as a consequence, all the blocks of the ddCOSMO matrix concerning non-intersecting spheres are zero, and the matrix is block-sparse. The right-hand side of the ddCOSMO linear system is assembled from the molecular potential, the W_n^{jk} coefficients, and the spherical harmonics:

$$[g_j]_l^m = -\sum_{n=1}^{N_s} w_n Y_l^m(\mathbf{y}_n) U_n^j \Phi_n^j \quad (\text{A11})$$

where $U_n^j = 1 - \sum_{k \in N_j} W_n^{jk}$, N_j is the list of spheres that intersect Ω_j , and Φ_n^j is the potential of the solute at \mathbf{y}_n on sphere Ω_j . It is now possible to write the discretized ddCOSMO linear system. Let $[X_j]_l^m$ be the $l - m$ expansion coefficient of σ_j in the spherical harmonics basis (i.e., the unknown of the ddCOSMO linear system): the ddCOSMO equation reads as

$$\begin{pmatrix} L_{11} & \dots & L_{1M} \\ \vdots & \ddots & \vdots \\ L_{M1} & \dots & L_{MM} \end{pmatrix} \begin{pmatrix} X_1 \\ \vdots \\ X_M \end{pmatrix} = \begin{pmatrix} g_1 \\ \vdots \\ g_M \end{pmatrix} \quad (\text{A12})$$

For the sake of brevity, and for convenience in the following manipulations, we introduce, for the ddCOSMO equation, the notation

$$LX = g$$

The solvation energy can now be computed as in eq A3, where, if the density of the solute is a collection of point multipoles, the integral can be easily computed. Let L_s be the maximum angular momentum of the solute's multipolar distribution (i.e.,

0 for point charges only, 2 for distributions up to the quadrupole) and let $[Q_j]_l^m$ be the $l - m$ (real, spherical) multipole on the j th atom of the solute. The polarization energy will be

$$\begin{aligned} E_s &= \frac{1}{2} f(\epsilon) \sum_{j=1}^M \sum_{l=0}^{L_s} \sum_{m=-l}^l \frac{4\pi}{2l+1} [Q_j]_l^m [X_j]_l^m \\ &= \frac{1}{2} f(\epsilon) \langle \Psi, X \rangle \end{aligned} \quad (\text{A13})$$

where, for each $0 \leq l \leq N$, $-l \leq m \leq l$, we have introduced the vector Ψ such that

$$[\Psi_j]_l^m = \frac{4\pi}{2l+1} [Q_j]_l^m \delta_{l \leq L_s} \quad (\text{A14})$$

$\delta_{l \leq L_s} = 1$ if $l \leq L_s$ and $\delta_{l \leq L_s} = 0$ otherwise. Here, we use the notation

$$\langle a, b \rangle = \sum_{j=1}^M \sum_{l=0}^N \sum_{m=-l}^l [a_j]_l^m [b_j]_l^m$$

■ APPENDIX B: DERIVATION OF THE COUPLED EQUATIONS

In this appendix, we will derive the coupled polarization equations for a variational force field. We recall that the COSMO field \mathbf{E}_c is obtained by differentiating the COSMO energy, with respect to the induced dipoles:

$$\begin{aligned} \mathbf{E}_c &= \frac{1}{2} f(\epsilon) \frac{\partial}{\partial \mu} \langle \Psi, X \rangle \\ &= \frac{1}{2} f(\epsilon) \left[\left\langle \frac{\partial \Psi}{\partial \mu}, X \right\rangle + \left\langle \Psi, \frac{\partial X}{\partial \mu} \right\rangle \right] \end{aligned} \quad (\text{B1})$$

The first term of eq B1 is easily assembled:

$$[E_{c,j}]_l^m = \frac{1}{2} f(\epsilon) \frac{4\pi}{3} [X_j]_l^m \quad (\text{B2})$$

Equation B2 introduces a linear transformation of the ddCOSMO X coefficients, which we denote using matrix A . Notice that we assume that the dipoles are in their spherical representation; in the actual implementation, the dipoles are treated as Cartesian multipoles and the spherical-to-Cartesian conversion is folded inside the matrix, so that we can write

$$\mathbf{E}_c^1 = \frac{1}{2} f(\epsilon) A X$$

We notice, from eq A14, that such a transformation is the adjoint of the transformation that, given the (Cartesian) induced dipoles, produces the vector Ψ_μ :

$$\Psi_\mu = A^* \mu$$

The second contribution to the COSMO field involves the derivatives of the X coefficients, with respect to the induced dipoles:

$$\left\langle \Psi, \frac{\partial X}{\partial \mu} \right\rangle = \left\langle \Psi, L^{-1} \frac{\partial g}{\partial \mu} \right\rangle = \left\langle S, \frac{\partial g}{\partial \mu} \right\rangle$$

where we have introduced the solution to the adjoint ddCOSMO linear system

$$L^* S = \Psi \quad (\text{B3})$$

The derivatives of g_μ are obtained by differentiating the solute's potential, with respect to the dipoles, and then assembling, with the potential derivative, a term such as that described in eq A11. In particular, let \vec{v}_n^{jk} be the vector pointing from the position of the k th atom to the gridpoint y_n on the j th sphere. The potential produced by the induced dipoles at the latter point is

$$[\Phi_\mu]_n^j = - \sum_{k=1}^M \frac{\vec{v}_n^{jk} \cdot \vec{\mu}_k}{|\vec{v}_n^{jk}|^3}$$

where, for convenience, we use the Cartesian representation of the dipoles, which allows us to compute the second contribution to the ddCOSMO field as

$$\vec{E}_{c,j}^2 = -\frac{1}{2}f(\epsilon) \sum_{k=1}^M \sum_{lm} \sum_{n=1}^{N_g} w_n Y_l^m(\mathbf{y}_n) U_n^k [S_k]_l^m \frac{\vec{v}_n^{jk}}{|\vec{v}_n^{jk}|^3} \quad (\text{B4})$$

As previously noted, eq B4 introduces a linear transformation that converts the solution to the ddCOSMO adjoint system into the second component of the COSMO field:

$$\mathbf{E}_c^2 = \frac{1}{2}f(\epsilon)B\mathbf{S}$$

Again, the adjoint of matrix B is the linear transformation that, given the (Cartesian) induced dipoles, produces the vector g_μ :

$$g_\mu = B^* \mu$$

ACKNOWLEDGMENTS

This work was also supported in part by French state funds managed by Calsimlab and the ANR within the Investissements d'Avenir program under reference ANR-11-IDEX-0004-02. Pengyu Ren is grateful for support by the Robert A. Welch Foundation (F-1691) and the National Institutes of Health (GM106137), as well as the high performance computing resources provided by TACC and XSEDE (TGMCB100057). Funding from French CNRS through a PICS grant between UPMC and UT Austin is acknowledged.
