Received: November 18, 2009

Affinities of alkali cations and halide anions for the peptide group were quantified using molecular dynamics simulations of aqueous solutions of *N*-methylacetamide using both nonpolarizable and polarizable force fields. Potassium and, more strongly, sodium exhibit an affinity for the carbonyl oxygen of the amide group, while none of the halide anions shows any appreciable attraction for the amide hydrogen. Heavier halides, however, interact with the hydrophobic methyl groups of *N*-methylacetamide. Using the present results for a model of the peptide bond we predict that the destabilizing effect of weakly hydrated Hofmeister ions, such as bromide or iodide, is not due to direct interactions with the backbone but rather due to attraction to hydrophobic regions of the protein.

## Introduction

Proteins can be destabilized by various chemical agents, such as urea or certain salts. Despite experimental and computational efforts the detailed molecular mechanisms of protein denaturation have not been fully established yet. Recent studies show that the most common denaturant, that is, urea interacts primarily with the protein backbone,<sup>1–4</sup> although contacts with nonpolar (particularly aromatic) side chains have been also found to be important.<sup>5–11</sup> However, the interaction between urea and the protein amide bond is not much stronger than that of water, which further complicates nailing down the denaturing mechanism. A recent spectroscopic study on a popular protein proxy, poly(*N*-isopropylacrylamide) in aqueous solutions of urea, indicates that the effect on protein folding and unfolding may be rather indirect and potentially also connected with entropic factors because of different sizes of urea and water molecules.<sup>4</sup>

Of denaturing salts, guanidinium chloride has been shown to be particularly efficient despite the fact that guanidinium does not seem to be strongly interacting with the protein backbone.<sup>2</sup> Guanidinium rather exhibits affinity for amino acid side chains, in particular aromatic ones.<sup>12</sup> Similar, albeit weaker destabilization of proteins is also caused by other ions such as large soft inorganic anions. An important question thus arises as to how common salts in water interact with the protein backbone<sup>13,14</sup> and whether contacts with the amide group are related to the denaturing ability of weakly hydrated ions in the Hofmeister series,<sup>15,16</sup> such as heavier halides, thiocyanate, perchlorate, etc.

*N*-methylacetamide (NMA) is one of the simplest molecules containing the amide group and has, therefore, been employed as a suitable model for studying interactions at the protein backbone.<sup>17–20</sup> On one hand, extensive MD simulations have

been performed in order to characterize pure liquid NMA<sup>21,22</sup> and aqueous NMA solutions.<sup>19</sup> The latter have been also complemented by integral equation theory<sup>23</sup> and NMR experiments.<sup>24</sup> On the other hand, interactions between NMA and selected inorganic ions such as alkali cations have been characterized in the gas phase<sup>25–27</sup> and in small water clusters.<sup>20</sup> The purpose of the present study is to fill the existing gap by simulating NMA in bulk aqueous solutions of alkali halides. By performing an extensive series of molecular dynamics (MD) simulations we attempt to address the question concerning interactions of common ions such as alkali cations and halide anions with the amide bond and their potential consequences for mechanisms of protein denaturation by chemical agents.

## Systems and Methods

We performed MD simulations of NMA as a proxy to the amide bond in proteins in aqueous alkali halide solutions. In particular, we simulated 1 M of NMA in 1 M solutions of NaCl, KCl, KBr, NaBr, and mixed solutions thereof. Additionally, we also simulated a single NMA in 1 M aqueous solutions of KF or NaI. To further check concentration effects, we did also test simulations of a single molecule of NMA in 1 M salt solutions.

Both nonpolarizable and polarizable force fields were employed in the present simulations. For NMA, the parm99 potential (without or with polarizability) was used with the molecule constructed from ACE and NME residues.<sup>28</sup> This potential, which is rather similar to those employed for NMA previously,<sup>19,21,22,29</sup> utilizes the same Lennard-Jones parameters as are used for the amide bond in proteins within the parm99 force field. For comparison, we also performed test simulations with a nonpolarizable parm99 force field for the NMA molecule, which has slightly different partial charges and Lennard-Jones parameters.<sup>28</sup> This did not change the binding patterns of alkali cations and halide anions to NMA in water. Quantitatively, the only notable difference was the reduction of the preference of Na<sup>+</sup> over K<sup>+</sup> for NMA, which can be traced primarily to the

increased van der Waals radius of the carbonyl oxygen in this parametrization.

For water, we employed either the nonpolarizable SPCE<sup>30</sup> or polarizable POL3<sup>31</sup> models. For sodium, potassium, chloride, and bromide we used practically the same parameters (without or with polarizability) as in our previous studies of ions in water.<sup>32,33</sup> For comparison and consistency check, we additionally performed simulations using other popular ion force fields<sup>34,35</sup> in combination with the TIP3P water model.<sup>36</sup> For reference, all employed ionic parameters with corresponding references are summarized in Table 1.

The total simulation time for each run was 100 ns (after equilibration of 1 ns) with a time step of 1 fs. The coordinates were saved every 1 ps yielding 100 000 frames for further analysis. By dividing this set of frames to 2–5 parts we checked that the simulation length was long enough to provide converged results. For the 1 M NMA in 1 M alkali halide solution the unit cell of  $26.3 \times 26.3 \times 26.3$  Å<sup>3</sup> contained approximately 400 water molecules, 8 NMA molecules, 8 cations, and 8 anions. 3D periodic boundary conditions were applied with long-range electrostatic interactions beyond the nonbonded cutoff of 9 Å accounted for using the Particle Mesh Ewald (PME) method.<sup>37</sup> The Berendsen temperature (300 K) and pressure (1 atm) couplings were used<sup>38</sup> and all bonds containing hydrogen were constrained using the SHAKE algorithm.<sup>39</sup>

The simulated trajectories were analyzed primarily in terms of radial distribution functions (RDF) and their integrals which provide the total number of the other species within a given distance from the investigated moiety. In particular, we have

evaluated the alkali cation–oxygen of the amide, halide anion–hydrogen of the amide, halide anion–methyl carbons, alkali cation–halide anion, and ion–water distributions, averaged over the production part of each trajectory. All MD simulations were performed using the Amber 10 program.<sup>40</sup>

## Results

Figures 1 and 2 shows radial distribution functions and integrals thereof between an alkali cation (sodium or potassium) and the electronegative carbonyl oxygen of the amide group, as obtained from MD simulations of 1 M of NMA in aqueous solutions of NaCl, KCl, NaBr, KBr, and NaCl/KBr mixture, all with salt concentration of 1 M. The principal result is that both cations exhibit an appreciable affinity for the carbonyl oxygen, as demonstrated by strong peaks at the RDFs corresponding to carbonyl oxygen–alkali cation contact pairs. This affinity is significantly stronger for Na<sup>+</sup> than K<sup>+</sup> as reflected in the integral curves, which provide the numbers of cations within a given distance from the carbonyl oxygen. Moreover, sodium wins over potassium both for contact and solvent-separated ion pairs, as is clear from the relative (Na<sup>+</sup> vs K<sup>+</sup>) heights of the first two RDF peaks and, particularly, from the fact that the plateau of the integral curve around 3.5 Å is higher for sodium than for potassium and the difference between the two curves further increases up to about 5 Å. These observations are robust with respect to change of a force field from a nonpolarizable (Figure 1) to a polarizable (Figure 2) model. Upon moving from single salt to mixed solutions the relative preference of the carbonyl oxygen of the amide group for sodium over potassium persists and, particularly for the nonpolarizable simulations, even becomes stronger. This points to a certain degree of competition between Na<sup>+</sup> and K<sup>+</sup> for the binding site at NMA, in which the former cation is a clear winner over the latter.

The fact that sodium binds more strongly to the carbonyl oxygen of the amide bond than potassium reflects itself not only in structural observables like RDFs but also in time-dependent properties such as the mean residence times of the ions in the vicinity of NMA. Figure 3 shows the distribution of contact times of Na<sup>+</sup> and K<sup>+</sup> with the carbonyl oxygen, as extracted from the nonpolarizable or polarizable simulation. To construct these distributions, we have followed all contact pairs between the carbonyl oxygen of NMA and an alkali cation (with separation smaller than 3.5 Å) transiently formed (for more than 5 ps) during

the simulations and histogrammed their durations. Consistently for both force fields the contacts with sodium are on average about

three times longer than those with potassium (residence times from exponential fits of  $\sim 37$  vs  $\sim 12$  ps, respectively).

**Figure 5.** Alkali cation–halide anion radial distribution functions and cumulative sums in pure and mixed solutions. Results from simulations with a nonpolarizable force field.

**Figure 6.** Alkali cation–halide anion radial distribution functions and cumulative sums in pure and mixed solutions. Results from simulations with a polarizable force field.

The interaction of the alkali cations with water molecules is practically unaffected by the chemical nature of the halide counteranion, at least at the 1 M concentration investigated here. This is demonstrated in Figure 4, which shows little change in sodium–water oxygen and potassium–water oxygen RDFs upon moving from single salt to mixed solutions, both in nonpolarizable and polarizable simulations. At a concentration of 1 M, pairing between alkali cations and halide anions is already non-negligible. Figures 5 and 6 show the cation–anion RDFs for nonpolarizable and polarizable simulations. One can see that potassium pairs more strongly than sodium with heavier halides (chloride and, in particular, bromide) with the effect of salt mixing being very small. Also, the influence of adding polarization is rather modest.

Figures 7 and 8 show the interaction between halide anions and the electropositive amide hydrogen in NMA. Unlike the alkali cations, chloride and bromide do not exhibit an appreciable affinity for the amide group, neither in nonpolarizable nor in polarizable simulations, the results of which are very similar to each other. For  $\text{Cl}^-$  the first peak at the RDF does not even cross unity (which corresponds to average bulk concentration) while it only barely does so for  $\text{Br}^-$ . Another potential site for attraction of heavier halides are the methyl

groups in NMA. While alkali cations are repelled from such hydrophobic groups, bromide and, to a lesser extent, also chloride exhibit an affinity for them, particularly in the polarizable calculations (Figures 9 and 10). Including polarization, the attraction of halides for the methyl groups becomes stronger and is now for both  $\text{Cl}^-$  and  $\text{Br}^-$  more significant than for the amide group. Like in the case of alkali cations, the water solvent shell around chloride and bromide is practically unaffected by moving from single salt to a mixed solution (Figure 11). However, changing the force field from nonpolarizable to polarizable slightly reduces the water density around the anions.

We have also investigated the possibility of pairing and aggregation of NMA molecules themselves in the aqueous salt solutions. The RDFs between amide hydrogen on one NMA and carbonyl oxygen of another NMA exhibit a weak tendency for pairing by forming intermolecular hydrogen bonds at the 1 M concentration of NMA, both in nonpolarizable and polarizable simulations (Figure 12). Nevertheless, to check the effect of this weak pairing on interactions with ions we have performed a very long simulation of just a single NMA molecule in a mixed NaCl/KCl solution of a total concentration of 1 M. The resulting alkali cation–carbonyl oxygen RDFs are very similar to those for 1 M NMA,

**Figure 7.** Amide hydrogen-halide anion radial distribution functions and cumulative sums in pure and mixed solutions. Results from simulations with a nonpolarizable force field.

indicating that the observed weak association of NMA molecules practically does not affect their interaction with dissolved ions.

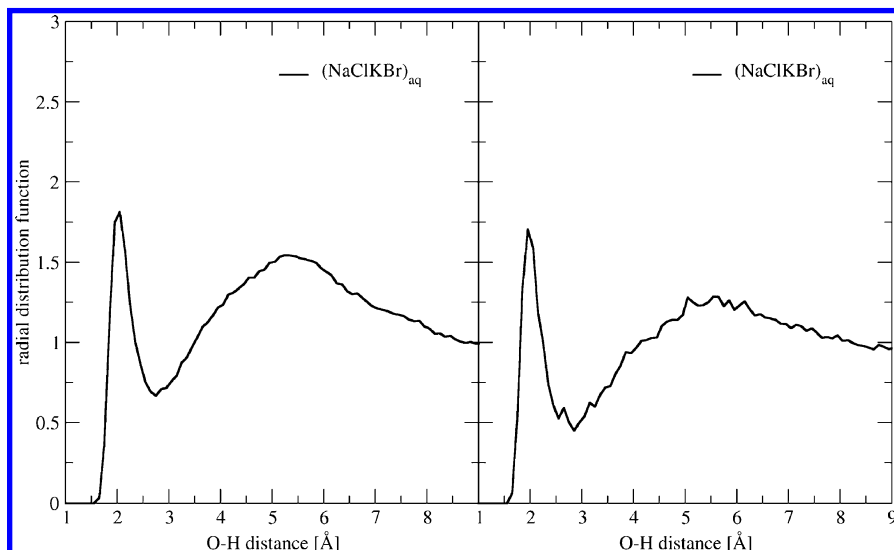

The lack of appreciable affinity of chloride and bromide for the amide bond raises the question whether halides that lie further from the center of the Hofmeister series, that is, fluoride

**Figure 10.** Methyl group carbon–halide anion radial distribution functions and cumulative sums in pure and mixed solutions. Results from simulations with a polarizable force field.

on one side and iodide on the other side, could not interact more strongly. To address this question, we have performed additional

polarizable simulations of 1 M NMA in 1 M KF or NaI solutions. The resulting halide anion–amide hydrogen RDFs

**Figure 13.** Amide hydrogen–fluoride or iodide (left) and methyl carbon–fluoride or iodide (right) radial distribution functions and cumulative sums in KF and NaI solutions. Results from simulations with a polarizable force field.

**Figure 14.** Carbonyl oxygen–alkali cation radial distribution functions and cumulative sums in KF and NaI solutions. Results from simulations with a polarizable force field.

depicted in Figure 13 demonstrate that even these “extreme” halides in the periodic table are no more attracted to the amide bond than chloride and bromide. Also, the presence of fluoride or iodide as counterions does not change the relative affinities of sodium versus potassium for the carbonyl oxygen in the amide bond. This follows from Figure 14 which compares the alkali cation–carbonyl oxygen RDFs in 1 M KF and NaI solutions. However, iodide does adsorb much more strongly to the hydrophobic groups of NMA than lighter halides, as demonstrated on the right panel of Figure 13 showing a strong peak on the iodide–methyl carbon RDF and the lack thereof for fluoride.

To further check the robustness of the present results with respect to the interaction potential, we have repeated the simulations of 1 M NMA in a mixed NaCl/KBr aqueous solution employing a somewhat different nonpolarizable force field for the ions than used above (see Table 1). The resulting ion–NMA affinities are in a quantitative agreement with the above results, as demonstrated by the alkali cation–carbonyl oxygen RDFs depicted in Figure 15.

## Discussion

Alkali cations exhibit an appreciable affinity and selectivity at the carbonyl oxygen of the peptide bond of NMA. This

**Figure 15.** Carbonyl oxygen–alkali cation radial distribution functions and cumulative sums in pure and mixed solutions. Results from simulations with a modified nonpolarizable force field.

attraction and preference of sodium over potassium is in accord with our previous observations of interactions of  $\text{Na}^+$  and  $\text{K}^+$  with surfaces of various proteins.<sup>41</sup> It is also consistent with analysis of amide solubility data using a thermodynamic partitioning model.<sup>42</sup> It is remarkable that the relative preference of sodium over potassium at the peptide bond is qualitatively the same as (albeit weaker than) that at the negatively charged carboxylate side chains of Glu and Asp. In other words, these two regions on protein surfaces work in concert in attracting and differentiating between alkali cations.

The present observation of the relatively low affinity of any of the halide anions for the amide hydrogen in NMA is surprising in light of a generally stronger effect of anions versus cations on protein stability. Our results indicate that, unlike urea, destabilizing anions such as bromide and iodide interact more strongly with hydrophobic moieties than with the peptide bond. Therefore, the molecular mechanism of protein destabilization and denaturation by ions may be different from that of the neutral urea molecule and may involve solubilization of hydrophobic regions of proteins by adsorption of large polarizable (soft) ions. A high affinity of iodide to nonpolar side chains has indeed been found to be a key component of denaturation of a  $\alpha$ -helical peptide in a recent simulation study of one of the

present authors.<sup>43</sup> Our findings are also consistent with earlier experiments emphasizing the importance of the nonpolar methyl groups for the halide anion-NMA interactions<sup>17</sup> and with the predictions from the thermodynamic partitioning model.<sup>42</sup>

The observed affinity of alkali cations to the peptide bond and lack thereof for halide anions is robustly predicted from both nonpolarizable and polarizable MD simulations, with the ion-amide RDFs being very similar to each other for the two force fields. The robustness of the results was also checked by switching between two somewhat different nonpolarizable force fields for ions. The only observable that was found to change significantly (i.e., increase) with the addition of polarization is the affinity of larger anions for hydrophobic methyl groups of NMA. This is yet another demonstration of the importance of polarization effects for segregation of ions at hydrophobic aqueous interfaces.<sup>44</sup> Finally, the observed trends in the relative strength of interactions of alkali cations and halide anions with the peptide bond in NMA depend only weakly on the particular counterion and concentration of salt or NMA.

## Conclusions

Using MD simulations of 100 ns duration we have obtained converged RDFs between alkali cations/halide anions and the amide bond of NMA in aqueous solutions. Using both nonpolarizable and polarizable force fields we have robustly shown that alkali cations show an appreciable affinity for the amide bond while the halide anions do not. Between sodium and potassium the former is the winner in terms of attraction for the carbonyl oxygen of NMA and this cation specificity is qualitatively the same as that at the carboxylate group of negatively charged amino acids Glu and Asp. The only appreciable interaction with NMA observed for anions was that of heavier halides with the hydrophobic methyl groups, particularly in the polarizable simulations.

Despite the fact that NMA is only a model for the peptide bond and the actual situation in proteins is much more complex we can conclude, based on the present results, that weakly hydrated Hofmeister anions (such as bromide or iodide) probably do not destabilize proteins via direct interactions with the backbone amide groups. We rather suggest that this destabilizing activity may be partly due to the affinity of large soft ions for hydrophobic groups and residues, which makes them more accessible to the aqueous solvent.
